

Plants

Section I: The Plant Kingdom

Plants are virtually everywhere – on land, in the ocean, and in freshwater. They supply food for other living things and habitats for insects and animals. Plants have three distinct characteristics. First, they are **multicellular**,

meaning they are made up of more than one cell. Secondly, they are **autotrophs** which means they make their own food. They use the process of photosynthesis, where they capture energy from the sun to make their food. Finally, they are **eukaryotic**, which means each cell has a nucleus containing DNA and other vital organelles.

A plant faces four significant challenges as an organism living on land. The first challenge is in their ability to obtain water and other nutrients. Plants developed adaptations like **roots** and **shoots** to limit water loss and absorb needed minerals. Roots absorb water and essential nutrients from the soil and carry them to other parts of the plant, enabling it to grow and develop.

Shoots consist of the leaves, stems, and flowers of the plant. Both are made of **vascular tissue**, a system of tube-shaped cells that branches throughout the plant. A vascular system is necessary for delivering essential resources to the plant.

Secondly, plants need to be able to support their bodies. Plants can only stand upright because of the production of **lignin**, a chemical that hardens the plant's cell walls. Thirdly, plants need to be able to maintain moisture, so their cellular processes must take place in an aqueous environment. As a result, plants have adapted a waxy **cuticle**, which acts as a waterproof layer coating the leaves and other above-ground parts of a plant. The **stomata**, microscopic pores in the leaf's surface, also prevent water loss by evaporation.

Plants

Section I: The Plant Kingdom Continued

Finally, plants must reproduce. Plants had to adapt to protect the gametes (eggs and sperm) from drying out. They also had to have some means for the dispersal or spreading out of seeds. Pollen grains are carried by wind or insects, so, more often than not, pollen grains never reach another flower. Therefore, a flower needs to make enough to increase the chances of pollen reaching another flower to ensure its survival.

Plants are classified as either **nonvascular** or **vascular**. Nonvascular plants evolved first and lacked a well-developed system for transporting water and minerals. They are generally small as a result. Vascular plants, however, have true vascular tissue allowing them to transport water and nutrients throughout the plant.

Plants also have complex life cycles that occur in two different stages. First, in the **sporophyte stage**, the plant produces spores or tiny cells that can grow into new organisms. Then, they develop into plants in the other phase, called the **gametophyte stage**. In this stage, the plant produces two kinds of sex cells - sperm cells and egg cells.

Review:

1. What three distinct characteristics do plants share?
2. Explain the function of vascular tissue in a plant.
3. Compare nonvascular and vascular plants.
